RESEARCH MEMORANDUMPERFORMANCE AND OPERATIONAL CHARACTERISTICS OF A PYTHON  
TURBINE-PROPELLER ENGINE AT SIMULATED  
ALTITUDE CONDITIONS

By Carl L. Meyer and LaVern A. Johnson

## SUMMARY

2308

The performance and operational characteristics of a Python turbine-propeller engine have been investigated over a range of engine operating conditions at simulated altitudes from 5000 to 40,000 feet in the NACA Lewis altitude wind tunnel. For the performance phase of the investigation, a single cowl-inlet ram pressure ratio was maintained and independent control of engine speed and fuel flow was used to obtain a range of power at each engine speed.

Engine performance data obtained at a given altitude could not be used to predict performance accurately at other altitudes by use of the standard air pressure and temperature generalizing factors.

Specific fuel consumption based on shaft horsepower decreased as the shaft horsepower increased at a given engine speed. At a given altitude condition and turbine-inlet total temperature, there was an optimum engine speed at which maximum shaft horsepower was obtained. At a given engine speed and turbine-inlet total temperature, a greater portion of the total available energy was converted to propulsive power as the altitude increased.

Windmilling starts were made at altitudes up to 40,000 feet; the minimum true airspeed required for successful windmilling starts increased as the altitude was raised. In general, the engine control prevented large overshoots or undershoots of engine speed during starts, accelerations, and decelerations.

## INTRODUCTION

An investigation to determine the performance and operational characteristics of a Python turbine-propeller engine over a range of simulated altitude conditions has been conducted in the NACA Lewis altitude wind tunnel. Instrumentation was installed in the engine to permit

evaluation of the performance of the individual components operating as integral parts of the engine as well as over-all engine performance. In the performance phase of the investigation, data were obtained over a range of engine speeds and exhaust-nozzle areas at altitudes from 10,000 to 40,000 feet at a single cowl-inlet ram pressure ratio; independent control of engine speed and fuel flow was used to obtain a range of power at each engine speed. Analyses of turbine, compressor, and combustion-chamber performance are presented in references 1, 2, and 3, respectively; and an investigation of the dynamic characteristics of the engine is reported in reference 4.

Performance and certain operational characteristics of the over-all engine are reported herein. Data are presented to show the performance of the engine over a range of engine speeds at each of four altitudes, the effect of altitude on nongeneralized performance at a given engine speed, the applicability of a generalization method for predicting engine performance at altitudes other than the test altitude, and the effect of exhaust-nozzle area on performance. Performance deterioration, apparently resulting from dust and oil accumulations in the compressor, is discussed. The division of energy between the propeller and jet is shown for a range of engine speeds, altitudes, and exhaust-nozzle areas. All engine performance data are also presented in tabular form. Operational characteristics discussed include windmilling drag and engine speed for a range of propeller blade angles, and starting, acceleration, and deceleration with the normal engine control system.

#### DESCRIPTION OF ENGINE

##### General

The main components of the Python turbine-propeller engine (fig. 1) are a 14-stage axial-flow compressor, 11 cylindrical combustion chambers, a two-stage turbine, an exhaust cone, a tail pipe with a fixed-area exit, and a reduction-gear assembly. The engine is fitted with two 4-blade, constant-speed, contra-rotating propellers. The maximum diameter of the engine is 54.5 inches, the length from the center line of the forward propeller to the end of the exhaust cone is  $182\frac{2}{3}$  inches, and the net dry weight without propellers is about 3150 pounds. For the engine used in the present investigation, the standard tail pipe has a length of 66 inches and an exit diameter of 23 inches.

The operating limits of the engine as established by the manufacturer are:

2308

Operating condition	Engine speed (rpm)	Tail-pipe gas temperature		Time limit (min)
		(°C)	(°F)	
Maximum take-off	8000	590	1094	5
Maximum climb	7800	560	1040	30
Maximum cruise	7600	530	986	continuous
Minimum flight idling	6500 ±100	---	---	---
Ground idling	3500 - 4000	580	1076	10

At maximum take-off operating conditions, the engine has a nominal static sea-level rating of 3670 shaft horsepower and 1150 pounds of jet thrust.

The engine is of the reverse-flow type (fig. 1). Air enters the engine through a screened annular cowling after which the air-flow passage is divided circumferentially into 11 convergent throats through which the air is swept inward through 180° to the entry annulus of the compressor. Thus, flow through the compressor is in the forward direction. Air from the compressor passes through an annular angled section where it is turned outward 90°, after which the air-flow passage is divided circumferentially into 11 combustion-chamber-inlet ducts through which the air is turned rearward 90° to the combustion chambers. Air is bled from the fifth compressor stage for cooling the rear bearing and rear face of the turbine disk and from the tenth compressor stage for cooling the front face of the turbine disk. A more complete description of the compressor is given in reference 2.

The 11 direct-flow-type combustion chambers (reference 3) are equally spaced around the outer circumference of the compressor casing. A vaporizing-type fuel system is used during normal engine operation; fuel from the main fuel nozzles and a portion of the air from the compressor enter the primary combustion zone through a mixing chamber or vaporizer. For starting purposes, nine combustion chambers include starting fuel nozzles and two chambers include combination spark plugs and starting fuel nozzles; cross-fire tubes are provided for ignition of the other combustion chambers. The fuel used throughout the investigation conformed to specification MIL-F-5616 (kerosene).

Gases from the combustion chambers flow through the two-stage turbine (reference 1) and exhaust to atmosphere through the exhaust cone and tail pipe. Each turbine stage consists of a stator and rotor; both rotor stages are mounted on a common disk.

The turbine shaft drives the compressor directly and the propeller shaft through a two-stage planetary-reduction gear. A floating-type annulus (or ring) gear in the reduction gear assembly is prevented from rotating by two hydraulic pistons which provide a means of determining shaft torque.

### Control

Fuel flow is controlled by a flow-control unit, which is sensitive to throttle position and cowl-inlet total pressure, in conjunction with a variable displacement pump. During normal engine operation, fuel from the flow-control unit flows through a distributor where it is divided into 11 equal parts and distributed to each of the main fuel nozzles. During starting, the initial fuel flow is directly from the flow-control unit to the starting fuel nozzles; a spring loaded valve prevents fuel from entering the distributor during starting until the fuel pressure increases to a given value. An electro-hydraulic valve in the fuel line to the starting fuel nozzles permits flow only while the ignition is on.

230

A propeller constant-speed unit controls engine speed over a range from approximately 75 to 100 percent of full engine speed. At engine speeds between approximately 50 and 75 percent of full speed, propeller pitch is held constant by a fine pitch stop which is normally retractable to facilitate ground starting and landing; engine speeds within this range are controlled by fuel flow. Minimum flight idling engine speed is normally the minimum engine speed at which the constant speed unit is effective.

A single lever, or throttle, is normally used to operate the engine. The necessary relation between engine speed and fuel flow is obtained by connecting both the propeller constant-speed unit control and the fuel-flow throttle to a single lever through an oil-servo unit and suitable cam-operated linkages. The engine will operate at approximately 50 percent of full engine speed with the single control lever in the fully closed position. As the single lever is advanced through the first portion of its travel, engine speed will increase to about 75 percent of full speed but the propeller blade angle remains constant. As the lever is further advanced, the propeller blade angle and the engine speed are gradually increased, resulting in a progressive increase in power.

A reverse torque switch in the reduction gear causes the propeller blade angle to increase whenever the propeller windmills the engine. To make flight windmilling starts possible, the reverse torque switch is inoperative when the ignition is on.

The normal single-lever control was not flexible enough to be used throughout the various phases of the present investigation. For the performance investigation, the propeller fine pitch stop was omitted and the propeller constant-speed unit valve and the fuel throttle were separately operated to permit independent control of engine speed and fuel flow. For the windmilling investigation, the constant-speed unit valve was replaced by a manually operated valve with which it was possible to control the flow of hydraulic oil to the propeller and thus control propeller blade angle. For the investigation of starting, acceleration, and deceleration characteristics, the normal single-lever control and a 20° propeller fine pitch stop were used.

[Redacted]

## INSTALLATION AND INSTRUMENTATION

The altitude wind tunnel in which the investigation was conducted is a closed-throat return-flow tunnel with a test section 20 feet in diameter and 40 feet long. The engine was installed in a wing segment (fig. 2) that was supported in the test section by the tunnel balance frame. The normal cowling over the forward section of the engine and NACA designed cowling over the exhaust cone and tail pipe were used throughout the investigation. Air was supplied to the engine from the tunnel air stream.

Instrumentation for measuring steady-state pressures and temperatures was installed at various stations (fig. 1) within the engine. Schematic diagrams of the instrumentation at individual stations are shown in figure 3. Pressures at the cowl inlet and in the tail pipe were measured with water-filled manometers and those at the compressor outlet (or combustion-chamber inlet) and turbine inlet were measured with mercury-filled manometers; all pressures were photographically recorded. Temperatures at the cowl inlet and compressor outlet were measured with iron-constantan thermocouples and those in the tail pipe were measured with chromel-alumel thermocouples; all temperatures were automatically recorded with self-balancing potentiometers.

Engine speed was measured by means of a stroboscopic tachometer in conjunction with a continuously indicating tachometer. Torque was sensed by means of the built-in hydraulic torquemeter which had been calibrated by the manufacturer to give propeller-shaft torque in terms of torquemeter pressure; torquemeter pressure was measured by a Bourdon gage. Fuel flow was measured by calibrated rotameters. The instrument panel included a series of gages for an indication of various operating temperatures and pressures, including turbine-inlet temperature, compressor-discharge pressure, and distributor fuel pressure. For the windmilling investigation, propeller blade angle was sensed by an NACA indicator attached to one of the blades of the rear propeller.

## PROCEDURE

### Performance Investigation

Throughout the performance investigation, independent control of engine speed and fuel flow was used to obtain a range of fuel flows and, consequently, a range of powers at each engine speed. With the standard 23-inch-diameter tail pipe, which had no exhaust nozzle, performance data were obtained at engine speeds from 6800 to 8000 rpm at altitudes from 10,000 to 30,000 feet and at engine speeds from 7400 to 8000 rpm at an altitude of 40,000 feet; data were not obtained at engine speeds below 7400 rpm at an altitude of 40,000 feet because of the limited range of

powers available. With a 24-inch-diameter tail pipe and tail-pipe exit diameters of 20, 22, and 24 inches, performance data were obtained at engine speeds from 7600 to 8000 rpm at altitudes from 10,000 to 40,000 feet.

All performance data were obtained at a cowl-inlet ram pressure ratio of about 1.03. Ram pressure ratio is defined as the ratio of cowl-inlet (station 1) total pressure to free-stream (tunnel test section) static pressure. The cowl-inlet air temperatures were held at approximately NACA standard values corresponding to the simulated conditions at altitudes of 10,000 and 20,000 feet; for altitudes of 30,000 and 40,000 feet, the cowl-inlet air temperature was held at about  $440^{\circ}$  R. The value of ram pressure ratio is a compromise value selected from two considerations. First, a deteriorated condition of the tunnel drive fan prohibited more realistic values of ram pressure ratio for the present investigation. Second, it was considered desirable to select a ram pressure ratio which could be maintained over the range of altitudes, engine speeds, and engine powers. Tunnel refrigeration equipment had the capacity to reduce the air temperature to about  $415^{\circ}$  R; however, the time required to reduce the temperature and the desirability of selecting a temperature that could be maintained over the range of engine conditions resulted in a compromise at the higher altitudes.

23 of

Symbols and methods of calculation are given in the appendix.

#### Operational Investigation

The standard 23-inch-diameter tail pipe was used throughout the operational investigation.

Windmilling. - For the windmilling investigation, a manually operated valve was used to control propeller blade angle and, consequently, windmilling engine speed. Steady-state windmilling data were obtained over a range of propeller blade angles at altitudes from 10,000 to 40,000 feet at a true airspeed of about 135 miles per hour and at true airspeeds from 100 to 175 miles per hour at an altitude of 20,000 feet.

Starting, acceleration, and deceleration. - The normal single-lever control and a  $20^{\circ}$  propeller fine pitch stop were used. Windmilling starting characteristics were investigated at altitudes from 5000 to 40,000 feet at true airspeeds ranging from about 120 to 280 miles per hour. Acceleration characteristics were investigated within the aforementioned altitude range at true airspeeds ranging from about 130 to 290 miles per hour. Deceleration characteristics were investigated at altitudes from 5000 to 35,000 feet at true airspeeds from about 160 to 310 miles per hour. In all cases, the true airspeed is that immediately preceding the transient; no attempt was made to hold airspeed constant during the transient.

Before attempting a windmilling start, the altitude and airspeed conditions were established with the propeller at full-feathered blade angle. Then, in quick succession, the ignition was turned on, the fuel valve was opened, and the unfeathering pump was started to reduce propeller blade angle. A successful start was considered to be one from which the engine could be accelerated to an engine speed of approximately 6500 rpm. At established altitude and airspeed conditions, accelerations and decelerations were accomplished by rapid movement of the single-lever control to the proper positions. The data for the starts, accelerations, and decelerations were obtained by photographing a panel of instruments with a motion-picture camera at a rate of about 9 frames per second.

## RESULTS AND DISCUSSION

### Engine Performance

All engine performance data obtained with the various tail-pipe configurations are presented in table I.

The inlet air temperatures deviated from NACA standard values, particularly at altitudes of 30,000 and 40,000 feet for which the inlet-air temperature was held at about 440° R. Therefore, all performance data presented graphically in nongeneralized form have been adjusted to NACA standard conditions at the respective altitudes by the use of the factors  $\theta_a$  and  $\delta_a$  (see appendix). Performance data adjusted by this method may be somewhat different from data obtained under actual standard conditions because the effect of Reynolds number is not considered; however, the method permits a reasonable evaluation of the data at standard altitude conditions.

Engine deterioration. - During the early phase of the present investigation, loss of power at a given tail-pipe temperature was noted with increased engine operating time. This loss in power is associated with the accumulation of dust and oil on the compressor blading, resulting in reduced mass flow and pressure ratio. The amount of dust that passed through the engine may have been greater during the wind-tunnel investigation than would have been encountered under normal operating conditions. The variation of engine performance with operating time is shown in figure 4 as plots of air flow, fuel flow, turbine-inlet total temperature, ratio of shaft enthalpy drop to total enthalpy drop (see appendix), and jet thrust against shaft horsepower for various engine operating times; data are presented for altitudes of 10,000, 20,000, 30,000, and 40,000 feet.

The trend of engine performance with operating time was similar, in general, at altitudes from 10,000 to 30,000 feet (figs. 4(a) to 4(c)); however, the effect of operating time on performance decreased with

increasing altitude until at an altitude of 40,000 feet there was essentially no change in performance with increased operating time within the range noted (fig. 4(d)). In general and for a given shaft horsepower, as engine operating time increased, air flow decreased, fuel flow (and, consequently, specific fuel consumption based on shaft horsepower) was essentially unchanged, turbine-inlet temperature increased, the ratio of shaft enthalpy drop to total enthalpy drop increased slightly, and jet thrust decreased at altitudes of 10,000 to 30,000 feet. At a given turbine-inlet total temperature, both shaft horsepower and jet thrust decreased with increased operating time because of the loss in air flow.

Data are not available to indicate the effect of engine operating time on performance at all engine speeds for the various altitudes. It was not possible, therefore, to adjust the data so as to eliminate the effects of engine deterioration. In table I and where possible in the various figures, the approximate engine time is noted.

Engine performance maps. - Performance data for a range of engine speeds at an altitude of 10,000 feet are presented in figure 5 as plots of air flow, turbine-inlet total temperature, fuel flow, specific fuel consumption based on shaft horsepower, and jet thrust against shaft horsepower. A portion of these data and similar data for altitudes of 20,000, 30,000, and 40,000 feet have been crossplotted in figure 6 in the form of engine performance maps for each of the four altitudes. The performance maps selected show shaft horsepower against engine speed at various constant values of turbine-inlet total temperature, fuel flow, and jet thrust; these maps summarize engine performance at each of the four altitudes within the range of shaft horsepowers and engine speeds investigated.

Within operating temperature and engine speed limits and by use of independent control of engine speed and fuel flow, a given shaft horsepower is available over a range of engine speeds and a range of shaft horsepowers is available at a given engine speed. Turbine-inlet total temperature, fuel flow, and jet thrust increase nearly linearly with shaft horsepower at a given engine speed. Use of a normal single-lever control would restrict engine operation within the performance map to an operating line defined by a single available shaft horsepower at a given engine speed, altitude, and airspeed.

In general, shaft horsepower at a given fuel flow decreased with increasing engine speed. At a given altitude condition and turbine-inlet temperature, in general, there was an optimum engine speed at which maximum shaft horsepower was obtained; the maximum value of shaft horsepower occurred at higher engine speeds as the turbine-inlet total temperature increased. Jet thrust increased with increasing engine speed primarily because of the increased air flow. Specific fuel consumption

2308  
based on shaft horsepower at an altitude of 10,000 feet (fig. 5(d)) decreased with increasing shaft horsepower at a given speed and with decreasing engine speed at a given shaft horsepower. If jet thrust were accounted for in the specific fuel consumption, the effect of engine speed on specific fuel consumption would be smaller since jet thrust increases with engine speed at a given shaft horsepower. The minimum specific fuel consumption based on shaft horsepower was approximately 0.9 pound per hour per shaft horsepower at engine speeds of about 7600 to 8000 rpm. Air flow (fig. 5(a)) at a given engine speed decreases somewhat with increasing shaft horsepower because of the increased compressor-pressure ratio.

Altitude. - Performance data for an engine speed of about 7600 rpm at altitudes of 10,000, 20,000, 30,000, and 40,000 feet are presented in figure 7 as plots of air flow, turbine-inlet total temperature, fuel flow, specific fuel consumption based on shaft horsepower, and jet thrust against shaft horsepower. The relation between turbine-inlet total temperature and shaft horsepower was used to superimpose temperature contours on figures 7(c) to 7(e).

Air flow decreased slightly with increasing shaft horsepower, as previously discussed, and decreased with increasing altitude primarily because of the reduction in air density (fig. 7(a)). As altitude increased, the shaft horsepower at a given turbine-inlet total temperature and the fuel flow required to produce a given turbine-inlet total temperature decreased, primarily because of the reduced air flow (figs. 7(b) and 7(c)). At each altitude, the lowest values of specific fuel consumption based on shaft horsepower was obtained at or near maximum temperature and power. For a given turbine-inlet total temperature, the minimum specific fuel consumption based on shaft horsepower was obtained at an altitude near 30,000 feet (fig. 7(d)). Jet thrust increased nearly linearly with shaft horsepower at each altitude and decreased with increasing altitude at a given turbine-inlet total temperature or shaft horsepower (fig. 7(e)).

The factors  $\delta_0$  and  $\theta_0$  were applied to the performance data of figure 5 and to similar data for the other altitudes at which data were obtained. The resultant data were cross-plotted to obtain generalized performance parameters for each altitude at a corrected engine speed of 8300 rpm, which is approximately the maximum corrected engine speed at which data were obtained at an altitude of 10,000 feet. The variation of corrected turbine-inlet total temperature, corrected fuel flow, and corrected jet thrust with corrected shaft horsepower at a corrected engine speed of 8300 rpm is shown in figure 8 for altitudes of 10,000, 20,000, 30,000, and 40,000 feet and a cowl-inlet ram pressure ratio of about 1.03. For a given corrected shaft horsepower, the corrected turbine-inlet total temperature and corrected fuel flow increased and the corrected jet thrust decreased as the altitude was increased from

10,000 to 40,000 feet. The pressure and temperature generalizing factors  $\delta_0$  and  $\theta_0$  could not, therefore, be applied to data obtained at a given altitude to predict performance accurately at some other altitude.

Engine deterioration cannot be eliminated from figure 8. However, considering the results of figure 4, the corrected performance for an altitude of 40,000 feet should be relatively unaffected by deterioration; also, data for an altitude of 10,000 feet were obtained earliest in the investigation and therefore should not be seriously affected by deterioration. A relatively true indication of the effect of altitude on generalized performance, therefore, should be noted by comparison of the curves for altitudes of 10,000 and 40,000 feet in figure 8.

It is shown in reference 2 that an increase in altitude from 10,000 to 40,000 feet at a given corrected engine speed decreased compressor efficiency and corrected air flow over the range of corrected turbine-inlet total temperature. Reference 3 indicates a slight tendency for combustion efficiency to decrease with increasing altitude. The loss in compressor efficiency and corrected air flow with increasing altitude made it necessary that the corrected turbine-inlet total temperature increase to maintain a given corrected shaft horsepower. To permit the higher corrected turbine-inlet temperature at a given shaft horsepower and to account for any loss in combustion efficiency, the corrected fuel flow increased with increasing altitude. The loss in corrected jet thrust at a given corrected shaft horsepower was primarily due to the loss in corrected air flow.

Exhaust-nozzle area. - Engine performance data for exhaust-nozzle diameters of 20, 22, and 24 inches, obtained at an engine speed of about 7600 rpm and an altitude of 10,000 feet, are presented in figure 9 as plots of turbine-inlet total temperature, specific fuel consumption based on shaft horsepower, and jet thrust against shaft horsepower; turbine-inlet temperature contours are superimposed on the curves of specific fuel consumption and jet thrust.

At a given turbine-inlet total temperature, jet thrust and specific fuel consumption based on shaft horsepower decreased and shaft horsepower increased as the exhaust-nozzle area increased. If jet thrust were accounted for in the specific fuel consumption, the effect of exhaust-nozzle area on specific fuel consumption would be smaller. The greater available turbine-pressure ratio with large exhaust-nozzle area resulted in a greater percentage of the available power being delivered to the shaft and consequently less being available in the jet.

### Engine-Power Division

The division of power is expressed as the ratio of equivalent propeller-shaft enthalpy drop to total available enthalpy drop and the ratio of jet enthalpy drop to total available enthalpy drop. The method of calculating these ratios is given in the appendix.

The jet and shaft enthalpy-drop ratios are shown in figure 10 as functions of shaft horsepower for a range of corrected engine speeds at an altitude of 10,000 feet. In general, both jet and shaft enthalpy-drop ratios at a given engine speed increased with increasing shaft horsepower. At a given shaft horsepower, an increase in engine speed had essentially no effect on jet enthalpy-drop ratio, but reduced the shaft enthalpy-drop ratio because of the increasing power requirements of the compressor. The maximum total available enthalpy drop at any engine speed is limited by the operating temperature limits of the engine.

The jet and shaft enthalpy-drop ratios are shown in figure 11 as functions of shaft horsepower for a range of altitudes at an engine speed of about 7600 rpm; turbine-inlet total-temperature contours are superimposed on these curves. Though shaft horsepower at a given turbine-inlet total temperature decreased with increasing altitude, jet and shaft enthalpy-drop ratios at a given temperature, in general, increased with increasing altitude. Thus, a greater percentage of the total available enthalpy drop was converted to propulsive power as the altitude was increased at a given turbine-inlet temperature and engine speed.

The jet and shaft enthalpy-drop ratios are shown in figure 12 as functions of shaft horsepower for a range of exhaust-nozzle areas at an engine speed of about 7600 rpm and an altitude of 10,000 feet; turbine-inlet total-temperature contours are superimposed. At a given shaft horsepower or at a given turbine-inlet total temperature, the jet enthalpy-drop ratio decreased and the shaft enthalpy-drop ratio increased as the exhaust-nozzle area increased. As the exhaust-nozzle area was increased, the sum of jet and shaft enthalpy-drop ratios decreased at a given shaft horsepower and remained essentially constant at a given turbine-inlet total temperature.

### Engine Operational Characteristics

Windmilling. - Drag and engine speed against propeller blade angle are presented in figure 13 for windmilling conditions over a range of altitudes at a true airspeed of 135 miles per hour and over a range of true airspeeds at an altitude of 20,000 feet. The drag presented is

defined as the installation drag at a given propeller blade angle minus the installation drag at full-feathered propeller blade angle; installation drag was determined from tunnel balance-scale measurements.

In general, both drag and windmilling engine speed at a given propeller blade angle increased as the altitude decreased and as the true airspeed increased. Peak values of drag occurred at a propeller blade angle of about  $15^{\circ}$ ; peak values of windmilling engine speed occurred at a propeller blade angle of about  $22^{\circ}$ . Though windmilling runs were not made at true airspeeds above 175 miles per hour, the need for feathering the propeller to prevent excessive drag at any airspeed and possible overspeeding of the engine at higher true airspeeds is evident.

Starting. - The effect of altitude on the minimum true airspeed required for successful windmilling starts is shown in figure 14; the normal single-lever control and a  $20^{\circ}$  propeller fine pitch stop were used. Successful windmilling starts were obtainable at a true airspeed of about 120 miles per hour up to an altitude between 15,000 and 20,000 feet; windmilling starts were not attempted at lower airspeeds. As the altitude was increased from 20,000 to 40,000 feet, progressively higher true airspeeds were required for successful starts. For the marginal starts noted in figure 14, the engine was started and accelerated to an operable engine speed but excessive turbine-inlet temperatures were encountered. The investigation did not include the determination of possible maximum true airspeed for windmilling starts; successful windmilling starts were made at true airspeeds up to 280 miles per hour.

Flight conditions and various engine variables during windmilling starts are shown against time in figure 15 for two altitudes at an initial true airspeed of about 280 miles per hour and for two initial airspeeds at an altitude of 25,000 feet. The flight conditions noted are tunnel true airspeed and cowl-inlet ram pressure ratio. The engine variables noted include turbine-inlet temperature, compressor-outlet total pressure, distributor fuel pressure (an indication of fuel flow), and engine speed. It is to be noted that at low distributor fuel pressures, a small change in pressure causes a relatively large change in fuel flow. As previously discussed, the altitude and airspeed conditions were established at full-feathered propeller blade angle. Then, in quick succession, the ignition was turned on, the fuel valve was opened (single control lever fully closed), and the unfeathering pump was started. With the single control lever fully closed, the engine will normally accelerate to about 50 percent of maximum engine speed; therefore, the accelerations noted consist of essentially two phases. As the engine speed approached 50 percent, the single control lever was advanced to permit continued acceleration to an engine speed of about 6500 rpm. The camera was started manually at the same time as the

unfeathering pump. Since a measure of propeller blade angle was not available for these data, the actual beginning of the transient is not accurately defined; the zero time noted in the figures is the first frame of the film.

No attempt was made to maintain tunnel true airspeed constant during the transient; as the propeller blade angle decreased during the unfeathering process and as the engine speed increased during the acceleration, the blockage caused by the engine propeller caused the true airspeed to decrease. The airspeed reached a minimum before maximum engine speed was reached. Cowl-inlet ram pressure ratio remained nearly constant during the transient, varying a maximum of about 0.01.

The accuracy of the measurement of turbine-inlet temperature is questionable. It appears from the turbine-inlet temperature curve, however, that in some cases partial burning occurred for the first few seconds; full combustion, as indicated by a rapid rise in temperature, occurred after about 4 seconds at which time the engine was windmilling at an appreciable engine speed. Since the normal control was used, there was no large overshoot of turbine-inlet temperature or engine speed. The apparent "flat spot" in the fuel-distributor pressure curve for the low true airspeed at an altitude of 25,000 feet (fig. 15(b)) is apparently due to a leveling off of fuel flow before the single-lever control was advanced. In most cases, the camera was stopped before steady-state operation was obtained after the transient.

The time required for the start and acceleration, until an engine speed of 6500 rpm was initially obtained, increased from about 11 seconds at an altitude of 25,000 feet to about 15.5 seconds at an altitude of 35,000 feet for the same initial true airspeed of 280 miles per hour (fig. 15(a)); for an altitude of 25,000 feet, this time increased from about 11 seconds at an airspeed of 280 miles per hour to 34 seconds at an airspeed of 144 miles per hour (fig. 15(b)). The maximum turbine-inlet temperature encountered during the transients was about the same for the two altitudes and an airspeed of 280 miles per hour (fig. 15(a)), but was higher for the lower of the two airspeeds at an altitude of 25,000 feet (fig. 15(b)).

It was necessary that the reverse torque switch be inoperative during a windmilling start until the engine was driving the propeller; it was occasionally necessary, therefore, to hold the ignition on longer than normally or to use an additional switch to keep the reverse torque switch inoperative after the ignition was off.

Acceleration. - Flight conditions and various engine variables during accelerations, from an engine speed of 6600 to 6800 rpm to an engine speed of 8000 rpm, are shown in figure 16 for two altitudes at an initial true airspeed of about 290 miles per hour and for two initial

true airspeeds at an altitude of 25,000 feet. The tunnel true airspeed and the cowl-inlet ram pressure ratio tended to increase very slightly during the transient.

It was desired to make the accelerations by quick movement of the single control lever from its initial position to the position for rated engine speed and power. Trends of the fuel distributor pressure indicate that the fuel flow did not increase uniformly. Some overshoot of engine speed is apparent for each acceleration. Adequate data are available to note apparent steady-state operation after the transient only for the low airspeed at an altitude of 25,000 feet (fig. 16(b)).

The time required for the acceleration until an engine speed of 8000 rpm was initially obtained increased, for an airspeed of 290 miles per hour, from about 4.3 seconds at an altitude of 25,000 feet to about 7.8 seconds at an altitude of 35,000 feet (fig. 16(a)); for an altitude of 25,000 feet, this time increased from about 4.3 seconds at a true airspeed of 292 miles per hour to about 5.2 seconds at an airspeed of 158 miles per hour (fig. 16(b)).

Deceleration. - Flight conditions and various engine variables during decelerations, from an engine speed of 8000 rpm to an engine speed of 6600 to 6800 rpm, are shown in figure 17 for two true airspeeds at an altitude of 25,000 feet. The tunnel true airspeed and the cowl-inlet ram pressure ratio tended to decrease very slightly during the transients.

It was desired to make these decelerations by quick movement of the single control lever from its initial setting to the final setting. Trends of the fuel distributor pressure for the deceleration at the higher airspeed indicate that the control was not moved uniformly to its final setting; this trend is reflected by the remaining engine variables and thus the deceleration was not accomplished in the shortest possible time. The time required for a given deceleration apparently increased with increasing airspeed. For the decelerations shown, the control prevented any notable undershoot of engine speed.

#### SUMMARY OF RESULTS

The performance and operational characteristics of a Python turbine-propeller engine were investigated over a range of engine operating conditions at simulated altitudes from 5000 to 40,000 feet. The results of this investigation may be summarized as follows:

1. Engine performance data obtained at a given altitude could not be used to accurately predict performance at other altitudes by the application of the standard air pressure and temperature generalizing factors.

2. Turbine-inlet total temperature, fuel flow, and jet thrust increased and specific fuel consumption based on shaft horsepower decreased with increasing shaft horsepower at constant engine speed; air flow at a given engine speed decreased slightly with increasing shaft horsepower. Air flow and, consequently, jet thrust increased with increasing engine speed. For a given altitude condition and turbine-inlet total temperature, there was an optimum engine speed at which maximum shaft horsepower was obtained. For a given turbine-inlet total temperature and engine speed, there was an optimum altitude at which minimum specific fuel consumption based on shaft horsepower was obtained.

3. At a given altitude and shaft horsepower, increasing the engine speed lowered the portion of the total available energy absorbed by the propeller and had essentially no effect on the portion absorbed by the jet. As the altitude was increased at a given engine speed and turbine-inlet total temperature, a greater portion of the total available energy was converted to propulsive power.

4. For windmilling conditions, maximum values of drag and wind-milling engine speed occurred at propeller blade angles of about  $15^{\circ}$  and  $22^{\circ}$ , respectively.

5. Windmilling starts and accelerations were made at altitudes as high as 40,000 feet; decelerations were made at altitudes up to 35,000 feet. The minimum true airspeed required for successful windmilling starts increased with increasing altitude. The time required for windmilling starts and accelerations increased with increasing altitude and decreasing airspeed; for decelerations, the time required increased with increasing airspeed. In general, the engine control prevented large overshoots or undershoots of engine speed during starts, accelerations, and decelerations.

## APPENDIX - CALCULATIONS

## Symbols

The following symbols are used in this report:

A	cross-sectional area, sq ft
$C_T$	thermal expansion ratio, ratio of hot exhaust-nozzle area to cold exhaust-nozzle area
$c_p$	specific heat at constant pressure, Btu/(lb)(°R)
$D - D_f$	installation drag at a given propeller blade angle minus installation drag at full-feathered propeller blade angle
$F_J$	jet thrust, lb
$f_{TM}$	torquemeter calibration factor, (min/rev)(sq in./lb)(shp)
f/a	fuel-air ratio
g	acceleration due to gravity, 32.2 ft/sec <sup>2</sup>
ghp	gear horsepower
H	enthalpy, Btu/lb
J	mechanical equivalent of heat, 778 ft-lb/Btu
N	engine speed, rpm
P	total pressure, lb/sq ft absolute
p	static pressure, lb/sq ft absolute
$p_{TM}$	torquemeter pressure, lb/sq in. gage
R	gas constant, 53.4 ft-lb/(lb)(°R)
shp	shaft horsepower
T	total temperature, °R
$T_i$	indicated temperature, °R
t	static temperature, °R

V	velocity, ft/sec
$W_a$	air flow, lb/sec
$W_c$	compressor leakage air flow, lb/sec
$W_f$	fuel flow, lb/hr
$W_g$	gas flow, lb/sec
$W_{rb}$	rear-bearing cooling-air flow, lb/sec
$W_t$	turbine cooling-air flow, lb/sec
$\beta$	propeller blade angle, deg
$\gamma$	ratio of specific heats
$\delta_a$	ratio of absolute ambient static pressure to absolute static pressure of NACA standard atmosphere at the respective altitude
$\delta_0$	ratio of absolute ambient static pressure to absolute static pressure of NACA standard atmosphere at sea level
$\theta_a$	ratio of absolute ambient static temperature to absolute static temperature of NACA standard atmosphere at the respective altitude
$\theta_0$	ratio of absolute ambient static temperature to absolute static temperature of NACA standard atmosphere at sea level

## Subscripts:

j	jet
n	turbine nozzle
0	tunnel-test-section air stream
1	cowl or compressor inlet
2	compressor outlet or combustion-chamber inlet
3	turbine inlet or combustion-chamber outlet
5	tail pipe

The following performance parameters generalized to NACA standard sea-level conditions are used:

$F_J/\delta_0$	corrected jet thrust, lb
$N/\sqrt{\theta_0}$	corrected engine speed, rpm
$shp/\delta_0\sqrt{\theta_0}$	corrected shaft horsepower
$T_3/\theta_0$	corrected turbine-inlet total temperature, $^{\circ}\text{R}$
$W_{a,1}\sqrt{\theta_0}/\delta_0$	corrected air flow, lb/sec
$W_f/\delta_0\sqrt{\theta_0}$	corrected fuel flow, lb/hr

230f

#### Methods of Calculation

Shaft horsepower. - A hydraulic piston-type torquemeter located in the reduction gearing was used to sense shaft torque which, together with measured values of engine speed, permitted determination of shaft horsepower. The torquemeter had been calibrated by the engine manufacturer so that shaft torque could be determined from the torquemeter pressure. The relation between the torquemeter calibration factor and torquemeter pressure is shown in figure 18. The calibration factor includes the ratio of shaft torque to torque at the torquemeter station; torque at the torquemeter station varies directly with torquemeter pressure. Shaft horsepower was determined from the following relation:

$$shp = f_{TM} p_{TM} N \quad (1)$$

where  $p_{TM}$  and  $N$  were measured and  $f_{TM}$  was determined from figure 18.

The total horsepower delivered to the reduction gear by the turbine is greater than the shaft horsepower because of power losses in the reduction gearing, bearings, and so forth. The power loss was obtained from a calibration curve (fig. 19), furnished by the manufacturer, showing the ratio of power loss to shaft horsepower as a function of shaft horsepower. This curve had been calculated from a measurement of the oil temperature rise in, and the oil flow through, the gear box.

Temperatures. - Total temperatures were obtained from indicated temperatures by use of a thermocouple recovery factor of 0.85 and the relation:

$$T = \frac{T_1 \left( \frac{P}{P_1} \right)^{\frac{\gamma-1}{\gamma}}}{1 + 0.85 \left[ \left( \frac{P}{P_1} \right)^{\frac{\gamma-1}{\gamma}} - 1 \right]} \quad (2)$$

2.08  
Turbine-inlet total temperature was determined by assuming the turbine power equal to the sum of the power absorbed by the compressor, the propeller, and the losses in the reduction gearing:

$$W_{g,3}H_3 - W_{g,5}H_5 = (W_{a,2}H_2 - W_{a,1}H_1) + \frac{550(\text{shp} + \text{ghp})}{J} \quad (3)$$

Then

$$T_3 = H_3/c_p$$

Gas flow. - Gas flow through the tail pipe may be determined from pressure and temperature measurements at station 5 by use of the relation:

$$W_{g,5} = P_5 C_T A_5 \sqrt{\frac{2\gamma_5 g}{(\gamma_5-1)Rt_5} \left[ \left( \frac{P_5}{P_1} \right)^{\frac{\gamma_5-1}{\gamma_5}} - 1 \right]} \quad (4)$$

Gas flow or air flow at any station in the engine may be determined from  $W_{g,5}$  by proper consideration of various leakage and cooling air flows and engine fuel flow; turbine gas flow is

$$W_{g,3} = W_{g,5} - (W_c + W_t) \quad (5)$$

Gas flows determined by this method were of the proper order of magnitude but data scatter was considered excessive; the data scatter was attributed to difficulty in accurately measuring small impact pressures.

It was observed in reference 1 that the turbine nozzles were choked and that the effective turbine-nozzle flow area was constant for the range of engine and altitude conditions of the present investigation. The following equation was used in the final calculation of gas flow:

$$W_{g,3} = \frac{P_3 \sqrt{\gamma_3}}{\sqrt{T_3}} \sqrt{\frac{g}{R}} \frac{A_n}{\left(\frac{\gamma_3+1}{2}\right)^{\frac{2}{\gamma_3-1}}} \quad (6)$$

The average effective turbine-nozzle flow area  $A_n$  was calculated from this equation, using gas flows determined from equations (4) and (5), turbine-inlet temperatures based on gas flows from equation (4), and measured values of  $P_3$ . Using the average effective turbine-nozzle flow area thus determined, measured values of  $P_3$ , and turbine-inlet temperatures based on gas flows from equation (4), a new value of  $W_{g,3}$  was obtained from equation (6). Turbine-inlet temperatures based on the new values of  $W_{g,3}$  showed a negligible change when compared with the original values.

Air flow. - Air flow at station 1 may be determined from

$$W_{a,1} = W_{g,3} + W_{rb} + W_c + W_t - \frac{W_f}{3600} \quad (7)$$

This is the air flow used in the present report.

Jet thrust. - Jet thrust was determined from:

$$F_j = \frac{W_{g,5}}{g} V_j = \frac{W_{g,5}}{g} \sqrt{\frac{2\gamma_5 g R}{(\gamma_5-1)} \left[ \frac{T_5}{\left(\frac{P_5}{P_0}\right)^{\frac{\gamma_5-1}{\gamma_5}}} - 1 \right]} \quad (8)$$

where  $W_{g,5} = W_{g,3} + (W_c + W_t)$ .

Enthalpy ratios. - The enthalpy ratios were calculated in the following manner:

$$\frac{\text{Jet enthalpy drop}}{\text{Total enthalpy drop}} = \frac{H_5 - H_j}{H_3 - H_j}$$

$$\frac{\text{Shaft enthalpy drop}}{\text{Total enthalpy drop}} = \frac{\frac{550}{J} (\text{shp} + \text{ghp})}{H_3 - H_j}$$

where  $H_j$  represents the enthalpy of the jet based on the static temperature of the exhaust gas when  $p_j = p_0$ . All other enthalpies are based on total temperatures.
